International Association of Dental Traumatology guidelines for the management of traumatic dental injuries: 1. Fractures and luxations of permanent teeth

Abstract – Traumatic dental injuries (TDIs) of permanent teeth occur frequently in children and young adults. Crown fractures and luxations are the most commonly occurring of all dental injuries. Proper diagnosis, treatment planning and followup are important for improving a favorable outcome. Guidelines should assist dentists and patients in decision making and for providing the best care effectively and efficiently. The International Association of Dental Traumatology (IADT) has developed a consensus statement after a review of the dental literature and group discussions. Experienced researchers and clinicians from various specialties were included in the group. In cases where the data did not appear conclusive, recommendations were based on the consensus opinion of the IADT board members. The guidelines represent the best current evidence based on literature search and professional opinion. The primary goal of these guidelines is to delineate an approach for the immediate or urgent care of TDIs. In this first article, the IADT Guidelines for management of fractures and luxations of permanent teeth will be presented.

Key words: consensus; fracture; luxation; review; trauma; tooth

*Members of the Task Group.
Traumatic dental injuries (TDIs) occur with great frequency in preschool, school-age children, and young adults comprising 5% of all injuries for which people seek treatment (1, 2). A 12-year review of the literature reports that 25% of all school children experience dental trauma and 33% of adults have experienced trauma to the permanent dentition, with the majority of injuries occurring before age nineteen (3). Luxation injuries are the most common TDIs in the primary dentition, whereas crown fractures are more commonly reported for the permanent dentition (1, 4, 5) TDIs represent a challenge to clinicians worldwide. Consequently, proper diagnosis, treatment planning and follow up are critical to assure a favorable outcome.

Guidelines, among other things, should assist dentists, other healthcare professionals, and patients in decision making. Also, they should be credible, readily understandable, and practical with the aim of delivering appropriate care as effectively and efficiently as possible.

The following guidelines by the International Association of Dental Traumatology (IADT) represent an updated set of guidelines based on the original guidelines published in 2007 (6–8). The update was accomplished by doing a review of the current dental literature using EMBASE, MEDLINE, and PUBMED searches from 1996 to 2011 as well as a search of the journal of Dental Traumatology from 2000 to 2011. Search words included tooth fractures, root fractures, tooth luxation, lateral luxation and permanent teeth, intruded permanent teeth, and luxated permanent teeth.

The primary goal of these guidelines is to delineate an approach for the immediate or urgent care of TDIs. It is understood that subsequent treatment may require secondary and tertiary interventions involving specialist consultations, services, and/or materials/methods not always available to the primary treating clinician.

The IADT published its first set of guidelines in 2001 and updated them in 2007 (6–13). As with the previous guidelines, the working group included experienced investigators and clinicians from various dental specialties and general practice. This revision represents the best evidence based on the available literature and expert professional judgment. In cases where the data did not appear conclusive, recommendations are based on the consensus opinion of the working group followed by review by the members of the IADT Board of Directors. It is understood that guidelines are to be applied with evaluation of the specific clinical circumstances, clinicians’ judgment, and patients’ characteristics, including but not limited to compliance, finances, and understanding of the immediate and long-term outcomes of treatment alternatives versus non-treatment. The IADT cannot and does not guarantee favorable outcomes from strict adherence to the Guidelines, but believe that their application can maximize the chances of a favorable outcome.

Guidelines undergo periodic updates. These 2012 Guidelines in this journal will appear in three parts:

Part I: Fractures and luxations of permanent teeth
Part II: Avulsion of permanent teeth
Part III: Injuries in the primary dentition

Guidelines offer recommendations for diagnosis and treatment of specific TDIs; however, they do not provide the comprehensive nor detailed information found in textbooks, the scientific literature, and, most recently, the Dental Trauma Guide (DTG) that can be accessed on http://www.dentaltraumaguide.org. Additionally, the DTG, also available on the IADT’s web page http://www.iadt-dentaltrauma.org, provides a visual and animated documentation of treatment procedures as well as estimations of prognosis for the various TDIs.

General recommendations/considerations

Clinical examination

Detailed description of protocols, methods, and documentation for clinical assessment of TDIs can be found in current textbooks (1, 14, 15).

Radiographic examination

Several projections and angulations are routinely recommended, but the clinician should decide which radiographs are required for the individual. The following are suggested:

- Periapical radiograph with a 90° horizontal angle with central beam through the tooth in question.
- Occlusal view.
- Periapical radiograph with lateral angulations from the mesial or distal aspect of the tooth in question.

Emerging imaging modalities such as cone-beam computerized tomography (CBCT) provide enhanced visualization of TDIs, particularly root fractures and lateral luxations, monitoring of healing, and complications. Availability is limited, and its use not currently considered routine; however, specific information is available in the scientific literature (16, 17).

Splinting type and duration

Current evidence supports short-term, non-rigid splints for splinting of luxated, avulsed, and root-fractured teeth. While neither the specific type of splint nor the duration of splinting for root-fractured and luxated teeth are significantly related to healing outcomes, it is considered best practice to maintain the repositioned tooth in correct position, provide patient comfort and improved function (18, 19).

Use of antibiotics

There is limited evidence for use of systemic antibiotics in the management of luxation injuries and no evidence that antibiotic coverage improves outcomes for root-fractured teeth. Antibiotic use remains at the discretion of the clinician as TDIs are often accompanied by soft tissue and other associated injuries, which may require other surgical intervention. In addition, the patient’s medical status may warrant antibiotic coverage (19, 20).

Sensibility tests

Sensibility testing refers to tests (cold test and/or electric pulp test) attempting to determine the condition of the tooth in correct position, provide patient comfort and improved function (18, 19).
pulp. At the time of injury, sensibility tests frequently give no response indicating a transient lack of pulpal response. Therefore, at least two signs and symptoms are necessary to make the diagnosis of necrotic pulp. Regular follow up controls are required to make a pulpal diagnosis.

**Immature versus mature permanent teeth**

Every effort should be made to preserve pulpal vitality in the immature permanent tooth to ensure continuous root development. The vast majority of TDIs occur in children and teenagers where loss of a tooth has lifetime consequences. The immature permanent tooth has considerable capacity for healing after traumatic exposures secondary to TDIs are amenable to proven conservative pulp therapies that maintain vital pulp vitality. Extrusion, intrusion, and lateral luxation injuries to teeth with open apices which have suffered a severe TDI after which pulp necrosis is anticipated is amenable to preventive pulpectomy as root development is substantially completed.

**Pulp canal obliteration**

Pulp canal obliteration (PCO) occurs more frequently in teeth with open apices which have suffered a severe luxation injury. It usually indicates ongoing pulpal vitality. Extrusion, intrusion, and lateral luxation injuries have high rates of PCO (32, 33) Subluxated and crown-fractured teeth also may exhibit PCO, although with less frequency (34). Additionally, PCO is a common occurrence following root fractures (35, 36).

<td>Root fracture</td>
<td>The coronal segment may be mobile and may be displaced. The tooth may be tender to percussion. Bleeding from the gingival sulcus may be noted. Sensibility testing may give negative results initially, indicating transient or permanent neural damage. Monitoring the status of the pulp is recommended. Transient crown discoloration (red or gray) may occur.</td>
<td>The fracture involves the root of the tooth and is in a horizontal or oblique plane. Fractures that are in the horizontal plane can usually be detected in the regular periapical 90° angle film with the central beam through the tooth. This is usually the case with fractures in the cervical third of the root. If the plane of fracture is more oblique, which is common with apical third fractures, an occlusal view or radiographs with varying horizontal angles are more likely to demonstrate the fracture including those located in the middle third. Fracture lines may be located at any level, from the marginal bone to the root apex. In addition to the 3 angulations and occlusal films, additional views such as a panoramic radiograph can be helpful in determining the course and position of the fracture lines.</td>
<td>Reposition, if displaced, the coronal segment of the tooth as soon as possible. Check position radiographically. Stabilize the tooth with a flexible splint for 4 weeks. If the root fracture is near the cervical area of the tooth, stabilization is beneficial for a longer period of time (up to 4 months). It is advisable to monitor healing for at least 1 year to determine pulpal status. If pulp necrosis develops, root canal treatment of the coronal tooth segment to the fracture line is indicated to preserve the tooth.</td>
<td>4 weeks S, C** 6–8 weeks C** 4 months S**, C** 6 months C** 1 year C** 5 years C**</td>
<td>Positive response to pulp testing (false negative possible up to 3 months) Signs of repair between fractured segments Continue to next evaluation</td>
</tr>
<tr>
<td>Alveolar fracture</td>
<td>The fracture involves the alveolar bone and may extend to adjacent bone. Segment mobility and dislocation with several teeth moving together are common findings. An occlusal change because of misalignment the fractured alveolar segment is often noted. Sensibility testing may or may not be positive.</td>
<td></td>
<td>4 weeks S**, C** 6–8 weeks C** 4 months C** 6 months C** 1 year C** 5 years C**</td>
<td></td>

C**, clinical and radiographic examination; S*, splint removal; S**, splint removal in cervical third fractures.

*For crown-fractured teeth with concomitant luxation injury, use the luxation follow-up schedule.

**Whenever there is evidence of external inflammatory root resorption, root canal therapy should be initiated immediately, with the use of calcium hydroxide as an intra-canal medication.
Patient instructions
Patient compliance with follow-up visits and home care contributes to better healing following a TDI. Both patients and parents of young patients should be advised regarding care of the injured tooth/teeth for optimal healing, prevention of further injury by avoidance of participation in contact sports, meticulous oral hygiene, and rinsing with an antibacterial such as chlorhexidine gluconate 0.1% alcohol free for 1–2 weeks.

Additional resources
Besides the general recommendations mentioned earlier, clinicians are encouraged to access the DTG, the journal Dental Traumatology, and other journals for information pertaining to treatment delay (37), intrusive luxations 38–47), root fractures (48–52), pulpal management of fractured and luxated teeth (34, 53–64, splinting (18, 39, 65–68), and antibiotics (69).

Key words: avulsion; exarticulation; consensus; review; trauma; tooth

Abstract – Avulsion of permanent teeth is one of the most serious dental injuries, and a prompt and correct emergency management is very important for the prognosis. The International Association of Dental Traumatology (IADT) has developed a consensus statement after a review of the dental literature and group discussions. Experienced researchers and clinicians from various specialties were included in the task group. The guidelines represent the current best evidence and practice based on literature research and professionals’ opinion. In cases where the data did not appear conclusive, recommendations were based on the consensus opinion or majority decision of the task group. Finally, the IADT board members were giving their opinion and approval. The primary goal of these guidelines is to delineate an approach for the immediate or urgent care of avulsed permanent teeth.

*Members of the Task Group.
Avulsion of permanent teeth is seen in 0.5–3% of all dental injuries (1, 2). Numerous studies show that this injury is one of the most serious dental injuries, and the prognosis is very much dependent on the actions taken at the place of accident and promptly after the avulsion (2–27). Replantation is in most situations the treatment of choice, but cannot always be carried out immediately.

An appropriate emergency management and treatment plan are important for a good prognosis. There are also individual situations when replantation is not indicated (e.g., severe caries or periodontal disease, non-cooperating patient, severe medical conditions (e.g., immunosuppression and severe cardiac conditions) which must be dealt with individually. Replantation may successfully save the tooth, but it is important to realize that some of the replanted teeth have lower chances of long-term survival and may even be lost or extracted at a later stage.

Guidelines for the emergency management are useful for delivering the best care possible in an efficient manner. The International Association of Dental Traumatology (IADT) has developed a consensus statement after an update of the dental literature and discussions in expert groups. Experienced international researchers and clinicians from various specialties and general dentistry were included in the groups. In cases in which the data did not appear conclusive, recommendations were based on the consensus opinion and in some situations on majority decision among the IADT board members. All recommendations are not evidence based on a high level. The guidelines should therefore be seen as the current best evidence and practice based on literature research and professionals’ opinion.

Guidelines should assist dentists, other healthcare professionals, and patients in decision making. Also, they should be credible, readily understandable, and practical with the aim of delivering appropriate care as effectively and efficiently as possible.

It is understood that guidelines are to be applied with judgment of the specific clinical circumstances, clinicians’ judgments, and patients’ characteristics, including, but not limited to compliance, finances and understanding of the immediate and long-term outcomes of treatment alternatives vs non-treatment. The IADT cannot and does not guarantee favorable outcomes from strict adherence to the Guidelines, but believe that their application can maximize the chances of a favorable outcome. Guidelines undergo periodic updates. The following guidelines by the IADT represent an updated set of guidelines based on the original guidelines published in 2007 (28–30).

In this article, one of a series of three articles, the IADT Guidelines for management of avulsed permanent teeth are presented. Literature has been searched using Medline and Scopus databases using the search words: avulsion, exarticulation, and replantation. The task group has then discussed the emergency treatment in detail and reached consensus of what to recommend today as best practice for the emergency management. This text is aiming at giving the concise, short necessary advice for treatment in the emergency situation. More detailed description of protocols, methods, and documentation for clinical assessment and diagnosis of different dental injuries can be found in articles, textbooks, and manuals (2, 24) and in the interactive web site Dental Trauma Guide http://dentaltraumaguide.org.

The final decision regarding patient care remains primarily in the hand of the treating dentist. For ethical reasons, it is important that the dentist provides the patient and guardian with pertinent information relating to treatment so also the patient and guardian has as much influence in the decision-making process as possible.

First aid for avulsed teeth at the place of accident (2, 10, 24, 25, 31–55)

Dentists should always be prepared to give appropriate advice to the public about first aid for avulsed teeth. An avulsed permanent tooth is one of the few real emergency situations in dentistry. In addition to increasing the public awareness by, for example, mass media campaigns, healthcare professionals, guardians and teachers should receive information on how to proceed following these severe unexpected injuries. Also, instructions may be given by telephone to people at the emergency site. Immediate replantation is the best treatment at the place of accident. If for some reasons this cannot be carried out, there are alternatives such as using various storage media.

If a tooth is avulsed, make sure it is a permanent tooth (primary teeth should not be replanted).

• Keep the patient calm.
• Find the tooth and pick it up by the crown (the white part). Avoid touching the root.
• If the tooth is dirty, wash it briefly (max 10 s) under cold running water and reposition it. Try to encourage the patient/guardian to replant the tooth. Once the tooth is back in place, bite on a handkerchief to hold it in position.
• If this is not possible, or for other reasons when replantation of the avulsed tooth is not possible (e.g., an unconscious patient), place the tooth in a glass of milk or another suitable storage medium and bring with the patient to the emergency clinic. The tooth can also be transported in the mouth, keeping it inside the lip or cheek if the patient is conscious. If the patient is very young, he/she could swallow the tooth – therefore it is advisable to get the patient to spit in a container and place the tooth in it. Avoid storage in water!
• If there is access at the place of accident to special storage or transport media (e.g., tissue culture/transplant medium, Hanks balanced storage medium (HBSS or saline) such media can preferably be used.
• Seek emergency dental treatment immediately.
The poster ‘Save a Tooth’ is written for the public and is available in several languages: English, Spanish, Portuguese, French, Icelandic, Italian, Arabic, and Turkish and can be obtained at the IADT website: http://www.iadt-dentaltrauma.org.

Treatment guidelines for avulsed permanent teeth (56–95)

Choice of treatment is related to the maturity of the root (open or closed apex) and the condition of the periodontal ligament cells. The condition of the cells is depending on the storage medium and the time out of the mouth, especially the dry time is critical for survival of the cells. After a dry time of 60 min or more, all periodontal ligament (PDL) cells are non-viable. For this reason, the dry time of the tooth, before it was placed replanted or placed in a storage medium, is very important to assess from the patient’s history.

From a clinical point of view, it is important for the clinician to roughly assess the condition of the cells by classifying the avulsed tooth into one of the following three groups before starting treatment:

- The PDL cells are most likely viable (i.e., the tooth has been replanted immediately or after a very short time at the place of accident).
- The PDL cells may be viable but compromised. The tooth has been kept in storage medium (e.g., tissue culture medium, HBSS, saline, milk, or saliva and the total dry time has been < 60 min).
- The PDL cells are non-viable. Examples of this is when the trauma history tells us that the total extra-oral dry time has been more than 60 min regardless of if the tooth was stored in an additional medium or not, or if the storage medium was non-physiologic.

1. Treatment guidelines for avulsed permanent teeth with closed apex

1a. The tooth has been replanted before the patient’s arrival at the clinic

- Leave the tooth in place.
- Clean the area with water spray, saline, or chlorhexidine.
- Suture gingival lacerations, if present.
- Verify normal position of the replanted tooth both clinically and radiographically.
- Apply a flexible splint for up to 2 weeks (see Splinting).
- Administer systemic antibiotics (see Antibiotics).
- Check tetanus protection (see Tetanus).
- Give patient instructions (see Patient instructions).
- Initiate root canal treatment 7–10 days after replantation and before splint removal. (see Endodontic considerations).

Follow-up
See: Follow-up procedures.

1b. The tooth has been kept in a physiologic storage medium or osmolality balanced medium and/or stored dry, the extra-oral dry time has been less than 60 min

Physiologic storage media include tissue culture medium and cell transport media. Examples of osmolality balanced media are HBSS, saline, and milk. Saliva can also be used.

- Clean the root surface and apical foramen with a stream of saline and soak the tooth in saline thereby removing contamination and dead cells from the root surface.
- Administer local anesthesia.
- Irrigate the socket with saline.
- Examine the alveolar socket. If there is a fracture of the socket wall, reposition it with a suitable instrument.
- Replant the tooth slowly with slight digital pressure. Do not use force.
- Suture gingival lacerations, if present.
- Verify normal position of the replanted tooth both clinically and radiographically.
- Apply a flexible splint for up to 2 weeks, keep away from the gingiva.
- Administer systemic antibiotics (see Antibiotics).
- Check tetanus protection (see Tetanus).
- Give patient instructions (see Patient instructions).
- Initiate root canal treatment 7–10 days after replantation and before splint removal (see Endodontic considerations).

Follow-up
See: Follow-up procedures.

1c. Dry time longer than 60 min or other reasons suggesting non-viable cells

Delayed replantation has a poor long-term prognosis. The periodontal ligament will be necrotic and not expected to heal. The goal in delayed replantation is, in addition to restoring the tooth for esthetic, functional and psychological reasons, to maintain alveolar bone contour. However, the expected eventual outcome is ankylosis and resorption of the root and the tooth will be lost eventually.

The technique for delayed replantation is as follows:

- Remove attached non-viable soft tissue carefully, for example, with gauze. The best way to this has not yet been decided (see Future areas of research).
- Root canal treatment to the tooth can be carried out prior to replantation or later (see Endodontic considerations).
- In cases of delayed replantation, root canal treatment should be either carried out on the tooth prior to replantation or it can be carried out 7–10 days later like in other replantation situations (see Endodontic considerations).
Follow-up procedures. The reader is referred to textbooks.

Follow-up

See: Follow-up procedures.

In children and adolescents ankylosis is frequently associated with infra-position. Careful follow-up is required and good communication is necessary to ensure the patient and guardian of this likely outcome. Decoronation may be necessary later when infraposition (>1 mm) is seen. For more detailed information of this procedure, the reader is referred to textbooks.

2. Treatment guidelines for avulsed permanent teeth with an open apex

2a. The tooth has been replanted before the patient’s arrival at the clinic

- Leave the tooth in place.
- Clean the area with water spray, saline, or chlorhexidine.
- Suture gingival lacerations, if present.
- Verify normal position of the replanted tooth both clinically and radiographically.
- Apply a flexible splint for up to 2 weeks (see Splinting).
- Administer systemic antibiotics (see Antibiotics).
- Check tetanus protection (see Tetanus).
- Give patient instructions (see Patient instructions).
- The goal for replanting still-developing (immature) teeth in children is to allow for possible revascularization of the pulp space. If that does not occur, root canal treatment may be recommended (see Endodontic considerations).

Follow-up

See: Follow-up procedures.

2b. The tooth has been kept in a physiologic storage medium or osmolality balanced medium and/or stored dry, the extra-oral dry time has been <60 min

Physiologic storage media include tissue culture medium and cell transport media. Examples of osmolality balanced media are HBSS, saline, and milk. Saliva can also be used.

- If contaminated, clean the root surface and apical foramen with a stream of saline.
- Topical application of antibiotics has been shown to enhance chances for revascularization of the pulp and can be considered if available (see Antibiotics).
- Administer local anesthesia.
- Examine the alveolar socket.
- If there is a fracture of the socket wall, reposition it with a suitable instrument.
- Remove the coagulum in the socket and replant the tooth slowly with slight digital pressure.
- Suture gingival lacerations, especially in the cervical area.
- Verify normal position of the replanted tooth clinically and radiographically. Apply a flexible splint for up to 2 weeks (see Splinting).
- Administer systemic antibiotics (see Antibiotics).
- Check tetanus protection (see Tetanus).
- Give patient instructions (see Patient instructions).
- The goal for replanting still-developing (immature) teeth in children is to allow for possible revascularization of the pulp space. The risk of infection-related root resorption should be weighed up against the chances of revascularization. Such resorption is very rapid in teeth of children. If revascularization does not occur, root canal treatment may be recommended (see Endodontic considerations).

Follow-up

See Follow-up procedures.

2c. Dry time longer than 60 min or other reasons suggesting non-viable cells

Delayed replantation has a poor long-term prognosis. The periodontal ligament will be necrotic and not expected to heal. The goal in delayed replantation is to restore the tooth to the dentition for esthetic, functional, and psychological reasons and to maintain alveolar contour. The eventual outcome will be ankylosis and resorption of the root.

The technique for delayed replantation is as follows:

- Remove attached non-viable soft tissue carefully, for example, with gauze. The best way to this has not yet been decided (see Future areas of research).
- Root canal treatment to the tooth can be carried out prior to replantation or later (see Endodontic considerations).
- Administer local anesthesia.
- Remove the coagulum from the socket with a stream of saline. Examine the alveolar socket. If there is a fracture of the socket wall, reposition it with a suitable instrument.
- Replant the tooth slowly with slight digital pressure. Suture gingival laceration. Verify normal position of the replanted tooth clinically and radiographically.
• Stabilize the tooth for 4 weeks using a flexible splint (see Splinting).
• Administer systemic antibiotics (see Antibiotics).
• Check tetanus protection (see Tetanus).
• Give patient instructions (see Patient instructions).

To slow down osseous replacement of the tooth, treatment of the root surface with fluoride prior to replantation (2% sodium fluoride solution for 20 min) has been suggested but it should not be seen as an absolute recommendation.

**Follow-up**

See Follow-up procedures.

Ankylosis is unavoidable after delayed replantation and must be taken into consideration.

In children and adolescents ankylosis is frequently associated with infraposition. Careful follow-up is required and good communication is necessary to ensure the patient and guardian of this likely outcome. Decoronation may be necessary when infraposition (>1 mm) is seen. For more detailed information of this procedure the reader is referred to textbooks.

**Anesthetics (64–66)**

Patients and guardians are recommended by us to do replantation at the place of accident without anesthesia. In the clinic, however, where local anesthetics are available, there is no need to omit local anesthesia, especially as there are often concomitant injuries. Concern is sometimes raised whether there are risks of compromising healing by using vasoconstrictor in the anesthesia. Evidence is weak for omitting vasoconstrictor in the oral and maxillofacial region and must be further documented before any recommendations against the use of it can be given (see suggested future areas of research at the end of this article). Block anesthesia (e.g., infra-orbital nerve block) may be considered as an alternative to infiltration anesthesia in more severely injured areas and must be related to the clinicians’ experience of such blocking techniques.

**Antibiotics (67–76)**

The value of systemic administration of antibiotics in human after replantation is still questionable as clinical studies have not demonstrated its value. Experimental studies have, however, usually shown positive effects upon both periodontal and pulpal healing especially when administered topically. For this reason, antibiotics are in most situations recommended after replantation of teeth. In addition, the patient’s medical status or concomitant injuries may warrant antibiotic coverage.

For systemic administration, tetracycline is the first choice in appropriate dose for patient age and weight the first week, can be given as alternative to tetracycline.

Topical antibiotics (minocycline or doxycycline, 1 mg per 20 ml of saline for 5 min soak) appear experimentally to have a beneficial effect in increasing the chance of pulpal space revascularization and periodontal healing and may be considered in immature teeth (2b).

**Tetanus (2, 24, 25)**

Refer the patient to a physician for evaluation of need for a tetanus booster if the avulsed tooth has contacted soil or tetanus coverage is uncertain.

**Splinting of replanted teeth (77–83)**

It is considered best practice to maintain the repositioned tooth in correct position, provide patient comfort and improve function. Current evidence supports short-term, flexible splints for splinting of replanted teeth. Studies have shown that periodontal and pulpal healing is promoted if the replanted tooth is given a chance for slight motion and the splinting time is not too long. Given this there is so far no specific type of splint related to healing outcomes. The splint should be placed on the buccal surfaces of the maxillary teeth to enable lingual access for endodontic procedures and to avoid occlusal interference.

Replanted permanent teeth should be splinted up to 2 weeks. Various types of acid etch bonded splints have been widely used to stabilize avulsed teeth because they allow good oral hygiene and are well tolerated by the patients. For a detailed description of how to make a splint, the reader is referred to articles, textbooks, manuals, and the web site Dental Trauma Guide http://www.dentaltraumaguide.org.

**Patient instructions (2, 24, 25)**

Patient compliance with follow-up visits and home care contributes to satisfactory healing following an injury. Both patients and guardians of young patients should be advised regarding care of the replanted tooth for optimal healing and prevention of further injury.

- Avoid participation in contact sports.
- Soft diet for up to 2 weeks. Thereafter normal function as soon as possible.
- Brush teeth with a soft toothbrush after each meal.
- Use a chlorhexidine (0.1%) mouth rinse twice a day for 1 week.

**Endodontic considerations (62, 84–93)**

If root canal treatment is indicated (teeth with closed apex), the ideal time to begin treatment is 7–10 days postreplantation. Calcium hydroxide is recommended as an intra-canal medication for up to 1 month followed by root canal filling with an acceptable material. Alternatively if an antibiotic-corticosteroid paste is chosen to be used as an anti-inflammatory, anti-elastic intra-canal medicament, it may be placed immediately or shortly following replantation and left...
for at least 2 weeks. If the antibiotic in the paste is dechlorotetracycline, there is a risk of tooth discoloration and care should be taken to confine the paste to the root canal and avoid contact of the paste with the pulp chamber walls.

If the tooth has been dry for more than 60 min before replantation. The root canal treatment may be carried out extra-orally prior to replantation.

In teeth with open apexes, which have been replanted immediately or kept in appropriate storage media prior to replantation, pulp revascularization is possible. The risk of infection-related root resorption should be weighed up against the chances of obtaining pulp space revascularization. Such resorption is very rapid in teeth of children. For very immature teeth, root canal treatment should be avoided unless there is clinical or radiographic evidence of pulp necrosis.

**Follow-up procedures (2, 6–9, 24, 25)**

**Clinical control**

Replanted teeth should be monitored by clinical and radiographic control after 4 weeks, 3 months, 6 months, 1 year, and yearly thereafter. Clinical and radiographic examination will provide information to determine outcome. Evaluation may include the findings described as follows.

**Favorable outcome**

**Closed apex**

Asymptomatic, normal mobility, normal percussion sound. No radiographic evidence of resorption or periapical osteitis: the lamina dura should appear normal.

**Open apex**

Asymptomatic, normal mobility, normal percussion sound. Radiographic evidence of arrested or continued root formation and eruption. Pulp canal obliteration is to be expected.

**Unfavorable outcome**

**Closed apex**

Symptomatic, excessive mobility or no mobility (ankylosis) with high-pitched percussion sound. Radiographic evidence of resorption (inflammatory, infection-related resorption, or ankylosis-related replacement resorption). When ankylosis occurs in a growing patient, infraposition of the tooth is highly likely to occur leading to disturbance of alveolar and facial growth over the short-, medium-, and long term.

**Open apex**

Symptomatic, excessive mobility or no mobility (ankylosis) with high-pitched percussion sound. In the case of ankylosis, the crown of the tooth will appear to be in an infraposition. Radiographic evidence of resorption (inflammatory, infection-related resorption, or ankylosis-related replacement resorption) or absence of continued root formation. When ankylosis occurs in a growing patient, infraposition of the tooth is highly likely to occur leading to disturbance of alveolar and facial growth over the short-, medium-, and long term.

**Loss of tooth**

In cases where teeth are lost in the emergency phase or will be lost later after trauma, discussions with colleagues, where available, who have expertise with managing such cases is prudent especially in growing patients. Ideally these discussions should take place before the tooth shows signs of infraposition. Appropriate treatment options may include decoronation, autotransplantation, resin retained bridge, denture, orthodontic space closure with composite modification and sectional osteotomy. Such treatment decisions are based on a full discussion with the child and parents, clinician’s expertise and aim to keep all options open until maturity is reached. After growth is completed, implant treatment can also be considered. The clinician is referred to textbooks and articles for further readings regarding these procedures.

**Future areas of research – methods discussed but not included as recommendations in the guidelines this time**

A number of promising treatment procedures for avulsed teeth have been discussed in the consensus group. Some of these treatment suggestions do have certain experimental evidence, and some of them are even used today in clinical practice: according to the group members, there is currently insufficient weight or quality of clinical and/or experimental evidence for some of these methods to be recognized as recommendations in the guidelines this time. These and some other important fields are examples where the group advocates further research and documentation:

- Methods for removal of non-viable PDL.
- Conditioning the PDL with extra-oral storage in tissue culture media prior to replantation.
- Conditioning the PDL with enamel matrix protein prior to replantation for teeth with short extra-oral periods.
- Topical treatment of root surface with fluoride for teeth with long extra-oral period.
- Revascularization of pulp space and methods promoting this.
- Optimal splint types with regard to periodontal and pulpal healing.
- Effect on adrenaline content of local anesthesia on healing.
- Reducing the inflammation with corticosteroids.
- Extra-oral root filling of teeth with less than a 60 min drying period.
- Use of titanium posts for root elongation and as alternatives to conventional root canal treatment.
- Long-term development of alveolar crest following replantation and decoration.

Abstract – Traumatic injuries to the primary dentition present special problems and the management is often different as compared with the permanent dentition. The International Association of Dental Traumatology (IADT) has developed a consensus statement after a review of the dental literature and group discussions. Experienced researchers and clinicians from various specialties were included in the task group. In cases where the data did not appear conclusive, recommendations were based on the consensus opinion or majority decision of the task group. Finally, the IADT board members were giving their opinion and approval. The primary goal of these guidelines is to delineate an approach for the immediate or urgent care for management of primary teeth injuries. The IADT cannot and does not guarantee favorable outcomes from strict adherence to the guidelines, but believe that their application can maximize the chances of a positive outcome.

Key words: tooth; trauma; primary; luxation; fracture; review

*Members of the Task Group.
Trauma to the oral region occurs frequently and comprises 5% of all injuries for which people seek treatment (1–3). In preschool children, head and facial non-oral injuries make up as much as 40% of all somatic injuries (1–3). In the age group 0–6 years, oral injuries are ranked as the second most common injury covering 18% of all somatic injuries (1–3). Of the oral injuries, dental injuries are the most frequent, followed by oral soft-tissue injuries. Luxation injuries affecting both multiple teeth and surrounding soft tissues are mainly reported in children 1–3 years of age and are typically as a result of falls (2, 4–11). Emergency situations therefore present a challenge to clinicians worldwide. It is now recognized that child injuries are a major threat to child health and that they are a neglected public health problem (12). A healthcare professional’s decision on how to treat combined with parental consent and patient assent (13) is the preferred scenario encountered when facing pediatric emergencies (14).

Guidelines for the management of primary teeth injuries should assist dentists, other healthcare professionals, and parents or carers in decision making. They should be credible, readily understandable, and practical with the aim of delivering the best care possible in an efficient manner.

The International Association of Dental Traumatology (IADT) has developed an updated set of guidelines based on a review of the current dental literature utilizing EMBASE, MEDLINE, and PubMed searches from 1996 to 2011 as well as a search of the Journal of Dental Traumatology from 2000 to 2011. Search words included primary dentition, deciduous dentition, crown fracture, primary incisor fracture, tooth fractures, root fractures, tooth luxation, lateral luxation and primary teeth, intruded primary teeth, luxated primary teeth, tooth avulsion, and tooth/crown injuries. Additionally, some relevant articles prior to 1996, which have served as the basis for further research in the field of dental traumatology, as well as recent policy statements regarding holistic care and management of the injured child, were also included.

The IADT published its first set of guidelines in 2001 (15) and updated them in 2007 (16). As with the previous guidelines, the working group included experienced researchers and clinicians in pediatric dentistry and oral and maxillofacial surgery. This revision represents the best evidence from the available literature and expert professional judgement. In cases where the data did not appear conclusive, recommendations were based on the consensus opinion of the working group followed by review by the members of the IADT Board of Directors. It is understood that guidelines are to be applied with judgement of the specific clinical circumstances, clinicians’ prudence, and patients’ characteristics, including but not limited to compliance, finances and understanding of the immediate and long-term outcomes of treatment alternatives versus non-treatment. The IADT cannot and does not guarantee favorable outcomes from strict adherence to the guidelines, but believe that their application can maximize the chances of a positive outcome. Guidelines undergo periodic updates. These 2012 Guidelines in the journal Dental Traumatology appear in three parts:

Part I: Fractures and luxations of permanent teeth (Dent Traumatol 2012;28:issue 1)
Part II: Avulsion of permanent teeth (Dent Traumatol 2012;28:issue 2)
Part III: Injuries in the primary dentition (Dent Traumatol 2012;28:issue 3)

Guidelines offer recommendations for diagnosis and treatment of specific traumatic dental injuries (TDIs); however, they cannot provide comprehensive nor detailed information found in textbooks, scientific literature, and most recently the dental trauma guide (DTG).

The latter can be accessed on http://www.dentaltraumaguide.org. Additionally, the DTG is also available on the IADT web page (http://www.iadt-dentaltrauma.org) and provides a visual and animated documentation of treatment procedures as well as estimates of prognosis for the various TDIs.

Because the management of permanent and primary traumatized dentitions differs significantly, separate guidelines have been developed (Tables 1 and 2).

Special considerations for trauma to primary teeth

A young child is often difficult to examine and treat because of the lack of cooperation and because of fear. The situation is distressing for both the child and parents or carers (17).

Furthermore, there are varying conditions in different countries concerning economic and social aspects as well as treatment philosophies (7, 17, 18). However, child and family-centered pediatric practices and institutions should consider the best interests of children and prepare clinicians to ensure the fulfillment of children’s rights when treatment decisions are made (19).

It is important to keep in mind that there is a close relationship between the apex of the root of the injured primary tooth and the underlying permanent tooth germ. Tooth malformation, impacted teeth, and eruption disturbances in the developing permanent dentition are some of the consequences that can occur following severe injuries to primary teeth and/or alveolar bone (5, 20–23). White or yellow-brown discoloration of crown and hypoplasia of permanent incisors are, however, the most common sequelae following intrusion and avulsion of primary teeth in children during the ages of 1–3 years (21–27). Because of these potential sequelae, treatment selections should be aimed at minimizing any additional risks of further damage to the permanent successors. It is therefore not recommended, for instance, to replant an avulsed primary incisor (16, 28, 29).

A child’s maturity and ability to cope with the emergency situation, the time for shedding of the injured tooth, and the occlusion, are all important factors that influence treatment selection. Repeated trauma episodes are frequent in children. It should be taken into consideration if planning root canal treatment in an injured primary tooth.

because trauma recurrence will shorten the survival time for the primary tooth (30).

There is no consensus in the literature about best treatment for the traumatized primary dentition. Furthermore, children with dental injuries are not always brought in for treatment immediately, which may be due to the lack of access to dental care (31, 32). While some reports advocate routine tooth extraction, others stress the importance of a more conservative approach by saving primary teeth whenever possible (29, 33). Traumatic pulp exposures of primary incisors are rare but can be treated with partial pulpotomy (34). Pulpectomy with zinc oxide eugenol or calcium hydroxide/iodoform paste is recommended in some countries (30,35,36). However, if full cooperation of the child can not be achieved, extraction is usually the alternative option.

It has been demonstrated that most luxation injuries heal spontaneously (37, 38), avoiding the traumatic experience of a tooth extraction. The clinician’s skills and experience with pediatric patients is of outmost importance for managing the patient’s and the parents’ or carers’ behavior in the emergency situation (17). After an accurate diagnosis and explanation of various treatment options to the parents or carers, the clinician and parents or carers must decide the treatment planning for the child’s own benefit.

Guidelines for the clinician

These Guidelines contain recommendations for diagnosis and treatment of traumatic injuries in the primary dentition, for caries-free, healthy primary teeth, using proper examination procedures.

Clinical examination

Information about the examination of traumatic injuries in the primary dentition can be found in a number of current textbooks (4, 39). The possibility of child abuse should be considered when assessing children under the age of 5 years who present with intra-oral trauma affecting the lips, gums, tongue, palate, and severe tooth injuries (40–46).

Radiographic examination

A detailed radiographic examination is essential to establish the extent of the injury to the supporting tissues, the stage of root development, and the relation to the permanent successors. Depending on the child’s ability to cope with the procedure and the type of injury suspected, the clinician should decide which radiograph is required for confirming diagnosis. Always consider minimizing the risk of radiation to the child. Several angles are recommended. Select the appropriate radiographic examination:

1. 90° horizontal angle with central beam through the tooth in question (size 2 film, horizontal view)
2. Occlusal view (size 2 film, horizontal view)

3 Extra-oral lateral view of the tooth in question may reveal the relationship between the apex of the displaced tooth and the permanent tooth germ as well as the direction of dislocation (size 2 film, vertical view), but is seldom indicated as it rarely adds extra information.

Splinting

Splinting is used only for alveolar bone fractures and possibly for intra-alveolar root fractures.

Use of antibiotics

There is no evidence for the use of systemic antibiotics in the management of luxation injuries in the primary dentition. Antibiotic use remains at the discretion of the clinician as TDIs are often accompanied by soft tissue and other associated injuries that may require significant surgical intervention. In addition, the child’s medical status may warrant antibiotic coverage. Whenever possible, contact the pediatrician who may give recommendations for a specific medical condition.

Sensibility and percussion tests

Sensibility and percussion tests are not reliable in primary teeth because of the inconsistent results.

Crown discoloration

Although these Guidelines recommendations focus on the management of acute dental injuries, crown discoloration may be considered as it is a frequently asked question by the parents or carers, mainly for esthetic reasons. Discoloration is a common complication after luxation injuries (47–50). Such discoloration may fade, and the tooth may regain its original shade (8, 47, 50, 51). Teeth with persistent dark discoloration may remain asymptomatic clinically and radiographically or they may develop apical periodontitis (52, 53). There is an association between crown discoloration and pulp necrosis in traumatized primary teeth (48, 54). Unless associated infection exists, root canal treatment is not indicated (55).

Pulp canal obliteration

Pulp canal obliteration is common sequela to luxation injuries. It has been found to occur in 35–50% (48, 50, 53) and indicates ongoing pulp vitality (48, 56). A yellowish hue can be noted.

Parents’ instructions

Good healing following an injury to the teeth and oral tissues depends, in part, on good oral hygiene. To optimize healing, parents and carers should be advised regarding care of the injured tooth/teeth and the prevention of further injury by supervising potentially

<thead>
<tr>
<th>Clinical findings</th>
<th>Radiographic findings</th>
<th>Treatments</th>
<th>Follow up</th>
<th>Favorable Outcome</th>
<th>Unfavorable Outcome</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lateral luxation</td>
<td>• The tooth is displaced, usually in a palatal/lingual, or labial direction</td>
<td>Increased periodontal ligament space apically is best seen on the occlusal exposure. And an occlusal exposure can sometimes also show the position of the displaced tooth and its relation to the permanent successor</td>
<td>• If there is no occlusal interference, as is often the case in anterior open bite, the tooth is allowed to reposition spontaneously</td>
<td>1 week C 2–3 weeks C 6–8 weeks C +R 1 year C+R</td>
<td>• Asymptomatic  • Clinical and radiographic signs of normal or healed periodontium  • Transient discoloration might occur</td>
</tr>
<tr>
<td></td>
<td>• It will be immobile</td>
<td></td>
<td>• In case of minor occlusal interference, slight grinding is indicated  • When there is more severe occlusal interference, the tooth can be gently repositioned by combined labial and palatal pressure after the use of local anesthesia  • In severe displacement, when the crown is dislocated in a labial direction, extraction is the treatment of choice</td>
<td></td>
<td>• No continuing root development in immature teeth  • Dark discoloration of crown  • No treatment is needed unless apical periodontitis develops</td>
</tr>
<tr>
<td>Intrusive luxation</td>
<td>• The tooth is usually displaced through the labial bone plate, or can be impinging upon the succedaneous tooth bud</td>
<td>When the apex is displaced toward or through the labial bone plate, the apical tip can be visualized and the tooth appears shorter than its contra lateral. When the apex is displaced toward the permanent tooth germ, the apical tip cannot be visualized and the tooth appears elongated</td>
<td>If the apex is displaced toward or through the labial bone plate, the tooth is left for spontaneous repositioning. If the apex is displaced into the developing tooth germ, extract</td>
<td>1 week C 3–4 weeks C + R 6–8 weeks C 6 months C+R 1 year C+R and (C*)</td>
<td>• Tooth in place or erupting  • No or transient discoloration</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>• Tooth locked in place  • Persistent discoloration  • Radiographic signs of apical periodontitis  • Damage to the permanent successor</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Avulsion</td>
<td>• The tooth is completely out of the socket</td>
<td>A radiographic examination is essential to ensure that the missing tooth is not intruded</td>
<td>It is not recommended to replant avulsed primary teeth</td>
<td>1 week C 6 months C + R 1 year C + R and (C*)</td>
<td>Damage to the permanent successor</td>
</tr>

hazardous activities. Brushing with a soft brush and use of alcohol-free 0.1% chlorhexidine gluconate topically on the affected area with cotton swabs twice a day for 1 week are recommended to prevent accumulation of plaque and debris. A soft diet for 10 days and restriction in the use of an intra-oral pacifier are also recommended.

Parents or carers should be further advised about possible complications that may occur, like swelling, increased mobility, or sinus tracts. Children may not complain about pain; however, infection may be present, and parents or carers should watch for signs such as swelling of the gums; if present they should bring the children in for treatment.

Documentation that the parents and carers have been informed about possible complications in the development of the permanent teeth, especially following intrusion, avulsion, and alveolar fracture injuries, is very important.
